Abstract. Aromatic precursors are precisely in the skin of grapes and nearby cells, and therefore there is a greater expression of the varietal aromas and aromatic precursors when the wine passes through this skin contact, as well as changes in product color. The aim of this study was to evaluate the physical and chemical characteristics of Chardonnay wine that has gone through different periods of skin contact. Chardonnay grapes, grown in vineyards located in the town of Bagé, in Campanha Gaúcha, were de-stemmed, crushed and a sulfur dioxide (50 mg/L⁻¹) was added. The experimental design was a 4 x 3 factorial of 4 treatments with 3 repetitions: T1, the wine obtained directly from pressing machine; T2, skin contact for 2 days; T3, skin contact for 4 days and T4, skin contact for 6 days. After the end of malolactic fermentation wines went under −2 C for the tartaric stabilization. There were analyzed the variables alcohol, total acidity, volatile acidity, total polyphenols, glycerol, gluconic acid and 420, 520 and 620 colors by infrared spectroscopy method by Fourier transform and the means were compared by 5% Tukey test. There was a significant difference in variables alcohol, volatile acidit, glucanic acid and color index of 420 nm (yellow).

1. Introduction

Viticulture in Campanha Gaúcha, Rio Grande do Sul, Brazil, has expanded in the last decade and is currently the second largest producer of fine wines in this country. The region, situated in the parallel 31° South, is characterized by hot summers and with good sunlight, good thermal amplitude and favorable soil for quality viticulture (Giovannini & Manfroi, 2009). In addition, technological advances and the correct management in the vineyards allows the obtainance of high quality products that can compete in the domestic market. Currently, there are produced in the region red, white and rosé wines.

Still not widely produced in Brazil, a new product type that have received attention are the macerated along the alcoholic fermentation white wines. Its production process differs from white wines mainly by the existence of a time of maceration of the skins of grapes with wine / wine during alcoholic fermentation. This process phenolic compounds in wines and improves the beneficial antioxidant effect on human health related to these molecules (Ruzic, Skerget & Knez, 2001; Darias-Martín et al., 2000).

The aroma of wine depends on several factors, such as the development of the plant in the vineyard, oenological practices, farming, the usage of determined yeast in wine making, among others, but white wines pre-fermentation maceration has shown to be important for the increase in floral and fruity aromas (Selli, 2006).

Furthermore, Ribéreau-Gayon et al. (2003) stated that varietal aromas and other aromatic precursors are precisely located in the skin of grapes and in nearby cells, leading to greater intensity in wines made using this technique. This may explain the higher aromatic concentrations in orange wines, even if they are produced with neutral grapes.

There is little literature about this winemaking technique in Brazil, which leaves open space for research to determine the best cultivars to be used, the optimal production technology and the correct steeping time for the product to be interesting from a consumer point of view.

The objective of this study was to determine the optimal time of contact between wine and skin and evaluate its physic and chemical characteristics.

2. Methodology

Chardonnay grapes, grown in vineyards located in the town of Bagé, in campanha Gaúcha, were harvested at full maturity, on the morning of 11/2/2016, and transported in plastic boxes to Universidade Federal do Pampa, where they were kept in cold storage under the temperature of 5 C for 24 hours.

The grapes were separated in boxes and labeled in accordance with the treatment to which correspond, and 27 kg were used per treatment. The grapes were destemmed, crushed and added sulfur dioxide (50 mg/L⁻¹). It was inoculated 30g / hL⁻¹ of Saccharomyces cerevisiae, 30 g hL⁻¹. The treatments were packed in glass bottles with 14L capacity. Treatment 1 (T1) is obtained by direct pressing wine; T2, wine with maceration for 2 days; T3, maceration for 4 days and T4, maceration for six 6 days. Fermentations took place under controlled temperature (20 °C). Final pressing was performed in manual pressing equipment. Treatments were replicated three times, a total of 12 glass bottles with...

*Resultados seguidos de mesma letra na linha não diferiram entre si ao nível de 5% de probabilidade utilizando o teste de Tukey; **Resultados seguidos de diferentes letras na linha, diferiram entre a nível de 5% de probabilidade utilizando o teste de Tukey.

The variable glycerol did not differ statistically, which can be explained by the fact that all wines get in contact with the lees for the same period;

It was expected statistical differences in the variable Index of Total Polyphenols, which in fact is reported by Arnold & Noble (1979). This result was not found despite the prolonged contact with the skins for a white wine. A larger maceration for more days would probably increase the ITP.

As for color, the T3 differed from T, showing more intense yellow color (A420). The other shades, responsible for the red and blue colorations showed no statistical difference, as were expected since chardonnay is a white grape cultivar.

**4. Conclusions**

According to the results (Table 1), there was a significant difference in variables alcohol, volatile acidity, gluconic acid and color index of 420 nm (yellow). For other variables analyzed, there is no significant difference between treatments. Other tests should be performed, particularly to discuss the flavor profile of these wines and confirm the results herein. Obtaining quality wines boost the sector, allowing the use of the white grape skin in the production of a second product.
