Abstract. The aim of this study was to explore the effects of aerobic exercise on learning and memory of aging brain and the underlying potential mechanism. We adopted the method of intraperitoneal administration for 6 weeks to induce aging rat model and gave rats swimming exercise intervention in the process of aging modeling. Then the Morris Water Maze test, immunofluorescence, western blotting and real time PCR technology were adopted to estimate rats' learning and memory abilities and the expression levels of BDNF and SYP in hippocampus respectively. Compared with the aging model rats induced by D-gal administration, the rats subjected to swimming exercise in the process of aging modeling showed not only faster acquisition and better retention of the maze but also higher expression levels of BDNF and SYP in hippocampus. These findings provide evidence that aerobic exercise could ameliorate learning and memory deficits of aging rats induced by D-gal, which is related to aerobic exercise' promoting hippocampal BDNF and SYP expression.

1 Introduction

The decline in cognitive functions, especially learning and memory deficits, is prevalent among older adults, which results in degraded quality of life for them[1,2]. Therefore, how to slow down the impairments of learning and memory in the aging process to promote the development of cognitive function is one of the goals of public health. It has been demonstrated by both epidemiological and experimental studies that physical exercises contribute to achieving the goal[3,4], however, the underlying mechanism remains incompletely unclear.

It is well known that the learning and memory formation are based on the neuron synaptic plasticity[5]. Synaptophysin(SYP), one of the most widely used protein markers of synaptic plasticity in the brain, existing in almost all pre-synaptic membranes and vesicles, is thought essential for stimulating synapse formation and synaptic transmission process[6,7]. Previous studies have confirmed that the decrease of SYP in hippocampus, an important brain area responsible for learning and memory, is relevant to age-dependent impairments in learning and memory[8,9]. Whether aerobic exercise has influence on SYP in aging hippocampus still remains unknown.

Brain-derived neurotrophic factor (BDNF) plays a critical role in the survival, growth, differentiation and synaptic plasticity of mammalian neurons[10,11]. It is well documented that low

BDNF expression in brain involved in the learning and memory deficits in the process of aging [12]. Available data in the literature indicate that regular aerobic exercise may promote BDNF release in budding and adult hippocampus[13-15], but few experiments focus on the effects of exercises on BDNF expression in aging hippocampus.

The free radical theory of aging indicates that increase of free radicals and oxidative stress and decline of anti-oxidation function are the main factors leading to aging and even to shortening lifespan[16]. D-galactose (D-gal), a reducing sugar, is a naturally occurring metabolic substance in body. At high levels, it can result in the excessive production of oxygen free radicals that damage cellular lipids, proteins, and DNA, which eventually impairs normal function of macromolecules and cells[17]. It has been shown that prolonged systemic exposure of rodents to D-gal makes oxidative stress increase and anti-oxidation function decline, which causes brain cell biological membrane peroxide reaction, and finally results in degenerative changes of brain[17,18]. These changes are considerably similar to the symptoms in natural aging brain. Thus, the aging rodent model induced by D-gal is recognized as an ideal model for studying the mechanism underlying brain aging and the approach for anti-aging.

In the study, we have used the aging rat model induced by d-gal to verify directly the hypothesis that regular aerobic exercise intervention would ameliorate learning and memory deficits of aging rats via promoting SYP and BDNF expression in hippocampus.

2 Materials and methods

2.1 Animals and groups

Clean grade healthy adult male Sprague-Dawley rats, each weighing 280–320g, were purchased from the experimental animal center of Chengdu Dasuo Biological Technology Co. LTD(Chengdu, China; Animal production license: CSXK, 2012-24). All rats were kept in conditions of temperature (22–25°C) and humidity (45–65%) and 12h/12h light-dark cycle, with food and water available *ad libitum*. After acclimatization to the laboratory for 1 week, the rats were randomly divided into 3 groups: control(C) group, D-gal administration (D) group, D-gal administration with exercise (DE) group, 12 rats in each group. All procedures were performed in accordance with Animal Care and Use Guidelines in China.

2.2 D-gal administration

According to literature published[19], the study adopted the method of systemic injection of D-gal (sigma, USA) to establish aging rat model, with rats in group D and DE intraperitoneally injected with D-gal at dose of 100mg/kg. d(dissolved in 0.9% saline to 5% concentration, injection volume was 2 ml/kg. d) daily for 6 weeks to induce aging, whereas those in group C were intraperitoneally injected with 0.9% saline in the same volume with D-gal.

2.3 Exercise protocol

During the 6 weeks of D-gal administration, the rats in group DE were subjected to exercise intervention. The endurance swimming exercise training in a transparent glass tank (150cm in length, 60cm in width, 50cm in depth, with the water temperature kept at $33 \pm 1^\circ\text{C}$) was used in our study[19]. On the first day of training, the rats swam for 20min, and then the training duration was lengthened daily by 10min until each rat could swim continuously for 60min. Subsequently, rats swam 1h per day for 6 times a week (9:00–10:00 PM from Monday to Saturday).

2.4 Morris Water Maze (MWM) test

The MWM test, consisting of 6 consecutive days of oriented navigation trial and a 60s of probe trial, was performed to evaluate spatial learning and memory as described previously by Morris[20] with some modifications. The water maze was a black circular pool (150cm in diameter, 50cm in height) filled with opaque water at $23 \pm 1^\circ\text{C}$ and surrounded by various visual cues. Moreover, the tank was divided into 4 equal quadrants (marked respectively as E, S, W and N) with two imaginary perpendicular lines. During the oriented navigation trial, each rat participated in 4 trials per day to learn to locate the platform (9cm in diameter) that fixed in the quadrant E and submerged 1.5cm underneath the surface of water. The animal was gently placed into the pool at the midpoint of the edge of quadrant, changed for each trial, and was allowed a maximum of 120s to locate the platform. Rats failing to find the platform within 120s were guided towards it and remained there for 15s, the same period as was allowed for the successful animals. The time that it took the rat to arrive at the submerged platform (referred to as “escape latency”) and the swimming speed were recorded with a digital camera to evaluate spatial learning ability. 24hrs after the last navigation training trial, the platform was removed and each rat was subjected to the probe trial, during which the rats were placed into the tank at the midpoint of the edge of quadrant W and allowed to swim in the tank for 60s. The time spent in the target quadrant (quadrant E) and the time of crossing the location where the platform had been fixed were recorded as a measure of spatial memory.

2.5 Tissue sampling

Tissue samples were collected in the 24hrs after the MWM test, with all rats sacrificed by decapitation and the brains quickly removed from the skull. 6 whole brain samples per group were immersed in 4% paraformaldehyde for immunofluorescence assay, while the bilateral hippocampus of the other 6 brains were quickly dissected on ice and stored at -80°C for western blot and real-time PCR analysis.

2.6 Brain section and immunofluorescence assay for SYP

The brain tissue samples fixed in 4% paraformaldehyde were embedded in paraffin and coronally sectioned at $50\mu\text{m}$ thickness using a microtome (Leica, Wetzlar, Germany), and five tissue sections were selected at $30\mu\text{m}$ apart between +1.7 and +3.0mm posterior to the bregma referring to a mouse atlas[21]. SYP immunofluorescence staining was performed in accordance with the standard protocols. DAPI was used for nuclear staining. In the end, $20\mu\text{l}$ of glycerole was applied to each slide and a cover slip was sealed in place. In order to obtain accurate data, immunofluorescence staining was carried out carefully under the same conditions and fluorescence images were obtained by the OLYMPUS microscope and analyzed by using Image-Pro Plus 6.0 software. SYP immunoreactivity was evaluated by measuring the integral optical density (IOD) of SYP immuno positive contents.

2.7 Protein extraction and western blot analysis for SYP and BDNF

The right hippocampus samples stored at -80°C were used for BDNF and SYP protein quantification using western blot. Total protein in the hippocampus was extracted as previously described[19]. Protein content was measured by BCA assay (Thermo Scientific) according to the standard protocols. Sample containing $50\mu\text{g}$ proteins was electrophoresed on 5–20% gradient SDS-PAGE gels to separate and then blotted onto low-fluorescent polyvinylidene fluoride (PVDF) membranes. After having been blocked with 5% non-fat milk for 1h, the PVDF membrane was incubated overnight at 4°C with the anti-BDNF or anti-SYP antibody(both are polyclonal rabbit anti-rat antibody, diluted at 1:500, Santa Cruz, USA) and then incubated for another 2hrs with appropriate horseradish peroxidase-conjugated secondary antibody(polyclonal goat anti-rabbit IgG, diluted at 1:2000, Santa Cruz, USA). The membranes were visualized by using the enhanced chemiluminescence detection system (Pierce,USA). β -actin (polyclonal, diluted at 1:5000; Abcam, Cambridge, MA) was used for internal control. Integral

optical density (IOD) of immunoblots was quantified by using Quantity One Gel Imaging System (Bio Rad, USA) and was normalized to β -actin.

2.8 RNA Extraction and Real-Time PCR Analysis for BDNF mRNA

Remaining hippocampus samples stored at -80°C were used for BDNF mRNA using real-time PCR analysis. Total RNA in hippocampus was extracted using TRIZOL Reagent (TaKaRa, Japan). After removing genomic DNA residual using DNase I, RNA samples were reversely transcribed into complementary DNA (cDNA) using the iScriptTM cDNA Synthesis Kit (BIO-RAD, USA) in accordance with the manufacturer's protocols. Then the real-time PCR was carried out using GoTaq[®] qPCR Master Mix (Promega, USA) and CFX96 TouchTM Real-Time PCR Detection System (Bio-Rad, USA). After an initial incubating at 94°C for 10min, DNA samples were amplified for 40 cycles of 95°C denaturation for 15s, annealing at 60°C for 60s, 72°C extension for 1min. For each sample, the levels of BDNF mRNA were normalized against β -actin mRNA levels using the $2^{-\Delta\Delta\text{Ct}}$ method [22]. The sequences of primers for RT-PCR amplification were as follows: BDNF (forward primer: 5'-AGC GTG TGT GAC AGT ATT AGC GAG-3' and reverse primer: 5'-ATG GGA TTA CAC TTG GTC TCG TAG A-3'), β -actin (forward primer: 5'-CGT AAA GAC CTC TAT GCC AAC A-3' and reverse primer: 5'-TAG GAG CCA GGG CAG TAA TC-3').

2.9 Data analysis

All values were reported as the means \pm standard deviation ($M \pm SD$). In terms of the data from the probe trials, western blot analysis and real-time PCR were made using a one-way analysis of variance (ANOVA) by SPSS (SPSS Inc, Chicago, IL, USA) 19.0 for windows, while the data from oriented navigation trial was analysed with a two-way ANOVA. A value of $P < 0.05$ was considered statistically significant.

3 Results

3.1 Effects of aerobic exercise on spatial learning and memory ability

In the MWM navigation task, all animals' escape latencies gradually shortened (Figure 1a), indicating that each rat was able to learn to locate the submerged platform. The rats in the group C and DE showed maximal performance on day 3 and did not significantly improve thereafter, whereas those in group D improved at a lower pace, and reached maximal performance on day 5 (Figure 1a). Analysis of the average escape latencies demonstrates that the group D were significantly longer than the group C and DE on days 2, 3, and 4 of training ($p < 0.05$), while there was no statistical difference on days 1, 5 and 6 among these groups as regards ($p > 0.05$). There was no significant difference in swimming speed among 3 groups during the 6-day training period (Figure 1b), suggesting that the escape latencies were not influenced by swimming velocity. In the probe trial, the rats in group D spent less time in the target quadrant compared with both group C and DE ($p < 0.05$), however, there was no remarkable difference in that between group DE and C (Figure 1c). In addition, rats in group C and DE crossed where the platform was fixed more often than group D ($p < 0.05$) (Figure 1b). Taken together, these data suggested that D-gal administration of 6 consecutive weeks impaired spatial learning and memory, while the aerobic exercise ameliorated the learning and memory impairment caused by D-gal administration.

(c) Number of crossings platform in the target quadrant during 60 seconds probe trail. (d) The time spent in the target quadrant during probe trial. ◆ $P < 0.05$, ◆◆ $P < 0.01$, vs. the group C; ▲ $P < 0.05$, vs. the group DE; ★ $P < 0.05$, vs. the group D.

3.2 Effects of Aerobic Exercise on SYP Protein Expression in Hippocampus

Under the laser confocal microscope, the immune positive products of SYP were observed to scattered distribution in hippocampus, and compared with group D, the fluorescence intensities of group C and group DE were more intense (Figure 2). Further analysis indicated that the IOD value of SYP immunofluorescence positive products in group D was lower than group C ($P < 0.01$), while that of group DE was significantly higher than group D ($P < 0.01$) (Figure 3a).

Consistent with the results of immunofluorescence assay, western blot analysis revealed that SYP protein in group D was significantly lower than both group C ($P < 0.01$) and DE ($p > 0.05$). There was no statistical difference between the group C and DE. The present results show that chronic administration D-gal caused the SYP expression levels in hippocampus decline, while exercise may upregulate SYP, a marker for synaptic plasticity in hippocampus thus reversed the downward to some extent caused by the D-gal treated (Figure 3b).

3.3 Effects of Aerobic Exercise on BDNF protein and mRNA Levels in Hippocampus

According to Western blot analysis, the rats in group D had obviously less BDNF level in hippocampus than group C and DE ($P < 0.01$, $P < 0.05$; Figure 4a), and that the BDNF levels slightly declined in group DE compared with group C, however, these values did not reach statistical significance ($p > 0.05$; Figure 4a). Consistent with those of the west blot analysis, the results from real-time PCR showed that the levels of hippocampal BDNF mRNA were significantly declined in the group D compared with both group C and group DE ($p > 0.05$; Figure 4b). These findings demonstrated that D-gal administration restrains BDNF genetic transcription as well as protein synthesis, however, exercise intervention attenuated the inhibitions induced by D-gal administration.

4 Discussion

Nowadays, systemic D-gal administration is one of the most extensively used brain aging model building methods[17, 18]. Our previous studies have confirmed that rats injected with D-gal for 6 weeks resulted in deterioration of learning and memory capacity and increase of free radicals in the brain[19], which is similar to the performance in natural aging. In order to test the influence of aerobic exercise on the hippocampal SYP and BDNF of aging rats' and to explore the effects of aerobic exercise on learning and memory of aging brain and the potential mechanism underlying, we built the aging model in this way again and gave rats swimming exercise intervention in the process of aging modeling in the current study.

It is generally acknowledged that synapse is the key structure of neuron networking and information transmission and that neuronal synaptic plasticity is the important part of neurobiology for learning and memory ability[10,11]. Many studies have implicated a contribution of synaptic plasticity reduction in learning and memory dysfunction in the aging process[23, 24]. SYP, a membrane protein with 38kD molecular weight, distributes nearly in all pre-synaptic terminals and is involved in synapse formation, neurotransmitter release and synaptic vesicle cycle[6,7], etc. At present, SYP is recognized as a reliable marker protein for synaptic plasticity in the brain and often used to qualitatively or quantitatively analyze synaptic density and distribution[6]. It has been shown that SYP levels in hippocampus decline with aging and present an age-dependent trend[25]. In the aging model induced by D-gal in our study, the hippocampal SYP expression is also down-regulated, suggesting that synapse degenerative changes in hippocampus, which may be an important cause of learning and memory impairment induced by D-gal treated.

Despite the fact that there is no way to stop the physiological brain aging process, yet numerous epidemiological surveys and experimental studies indicate that appropriate sports could delay the process of aging brain and improve the learning and memory ability[3, 4]. Consistent with what has been previously reported[19], rats' performance in MWM demonstrates that regular swimming exercise could prevent learning and memory impairment against brain senescence in the present study, and it is possible that this prevention effect for learning and memory impairment may be a consequence of improved synaptic plasticity and neurotransmission through the increase of SYP expression. This point is based on the observation that both immunofluorescence and western blot assay of hippocampal SYP in the present study showed significantly higher expression level in rats that did exercise in the process of D-gal injection than rats that didn't exercise.

BDNF, one of the most abundant neurotrophin factors, widely distributing in the central nervous system, has been confirmed by animal studies that it could regulate hippocampal synaptic plasticity and cognitive function through multiple mechanisms[26,27], and its' expression level in hippocampus is closely related to the ability of learning and memory[10,11]. BDNF knockout mice exhibit decreases in the number of docked vesicles and in the levels of SYP and impairments in neurotransmitter release[28]. A lot of experimental results show that BDNF amount in brain, especially in hippocampus, is reduced in the aged[12,29,30]. Consistent with these results, we found that both BDNF mRNA and BDNF protein levels in hippocampus of aging model rats were significantly lower than the adult rats in the current study. Exercise has been found to increase hippocampal BDNF both in the growth period and adulthood. In the present study, we investigated the effect of aerobic exercise intervention on BDNF expression in hippocampus during the aging and the results demonstrated that aerobic exercise intervention in the aging process could prevent age-related hippocampal BDNF gene transcription and translation levels decrease in a certain extent. Further statistics show that the hippocampus BDNF levels were highly positively correlated to SYP. These results indicate that exercise induced-BDNF express involve in preventing aging-related hippocampal synaptic plasticity impairment and learning and memory decline.

In summary, the findings provide evidence that aerobic exercise ameliorates learning and memory deficits of aging rats induced by D-gal, which may be related to promoting hippocampal BDNF and SYP expression by aerobic exercise. However, further study is also needed to probe which BDNF signaling pathway is involved in the strengthening of synaptic plasticity and the improvement of learning and memory.
